INTRODUCTION

Purpose and Scope

The purpose of the study was to compare hydrologic, hydrogeologic, and geochemical conditions during the pre- and post-construction phases of structure S-331 and its effect on Canal 103, which is part of the South Dade Conveyance Canal System. Both geologic and hydrologic data were used to make this determination. This technical memorandum is intended to fulfill the requirements of data gathering and analysis during the pre-pumping period condition within the basin. This period of time is from 7/15/79 to 3/1/83. This memorandum report provides interpretation of the pre-structure data analysis of the C-103 Basin; however, a more in-depth report comparing the pre- versus the post-pumping conditions will be required in the future. This memorandum will serve as a working document when preparing the final report, once an adequate amount of post-pumping data is collected. All of the data gathered during the period of study is presented in this memorandum with the exception of the groundwater level and stage data, which are archived in the Data Management Computer Library.

Location and Extent of Study Area

The location of C-103 and the surrounding area is shown in Figure 1. The most western extent of C-103 is where it merges with L-31N canal approximately one mile north of the Homestead General Aviation Airport. The canal follows a bending southeasterly course of approximately 16 miles to the discharge point at Biscayne Bay. The control structures along C-103 include S-196, S-167, S-179, and S-20F. The study was performed west of S-167 to the L-31N canal. In this western portion the canal drains agricultural lands consisting of nurseries, truck farms, and avocado and mango groves. Portions north of Homestead drain urbanized developed lots. The eastern portion of C-103 is located just south of Homestead Air Base and is commonly referred to as Mowry Canal at the most eastern extent.

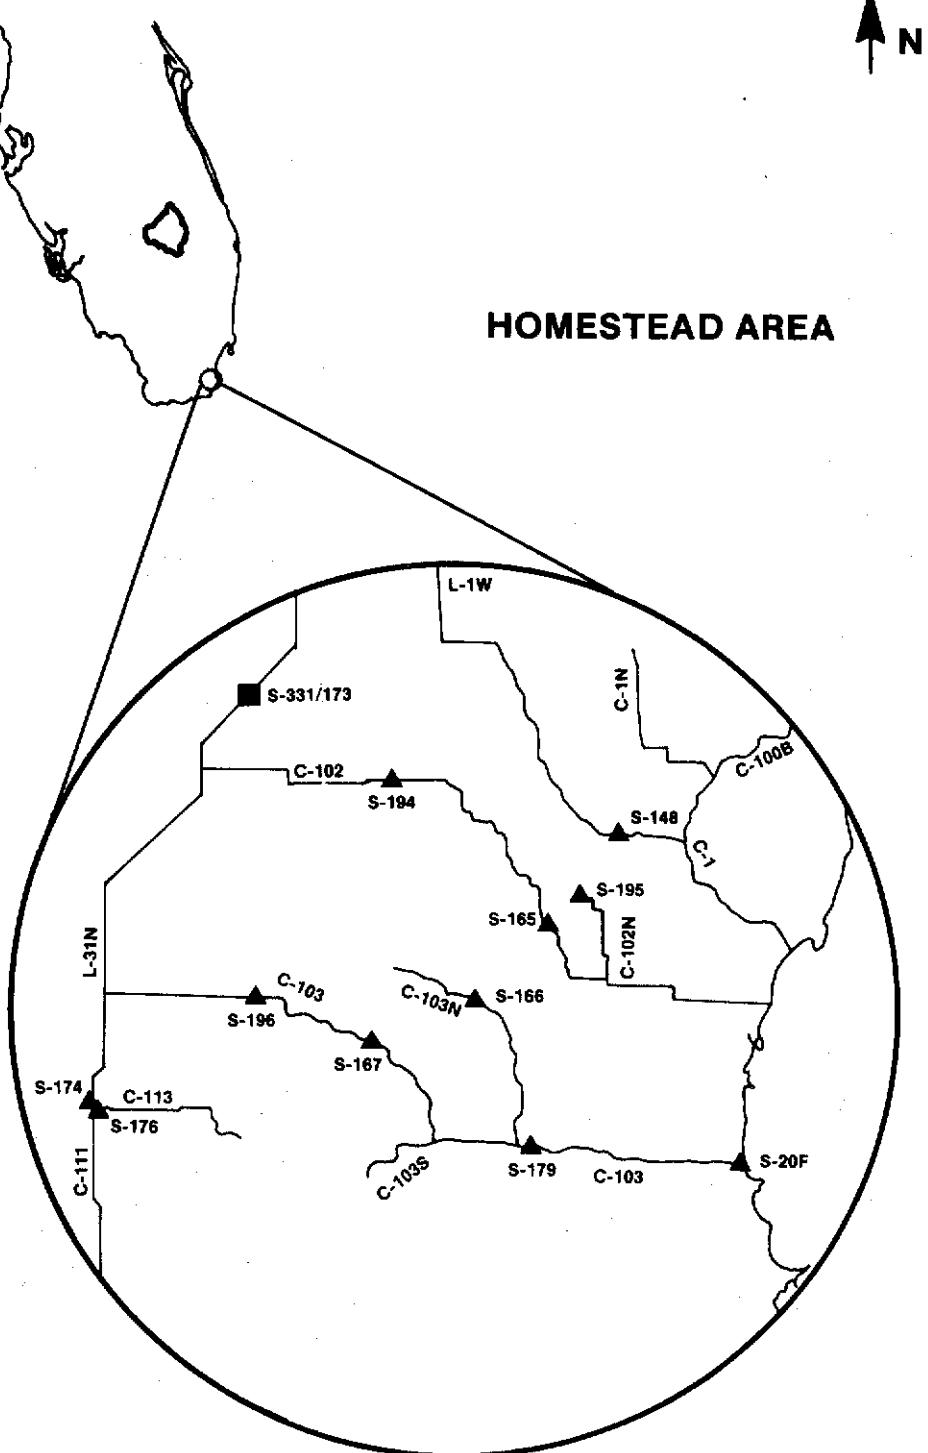

Figure 1 LOCATION OF STUDY AREA

MONITORING NETWORK

Groundwater Stations

A total of 23 wells were drilled at three different areas along C-103 for the project (Figure 2). The most extensive cross section (A) is at station 655+75 of C-103 where 17 wells were drilled. The next cross section (B) to the east is at station 588+00, and consists of four wells. The third and most eastern of the three cross sections (C) is located at station 495+00 and has two wells, both on the south side of C-103.

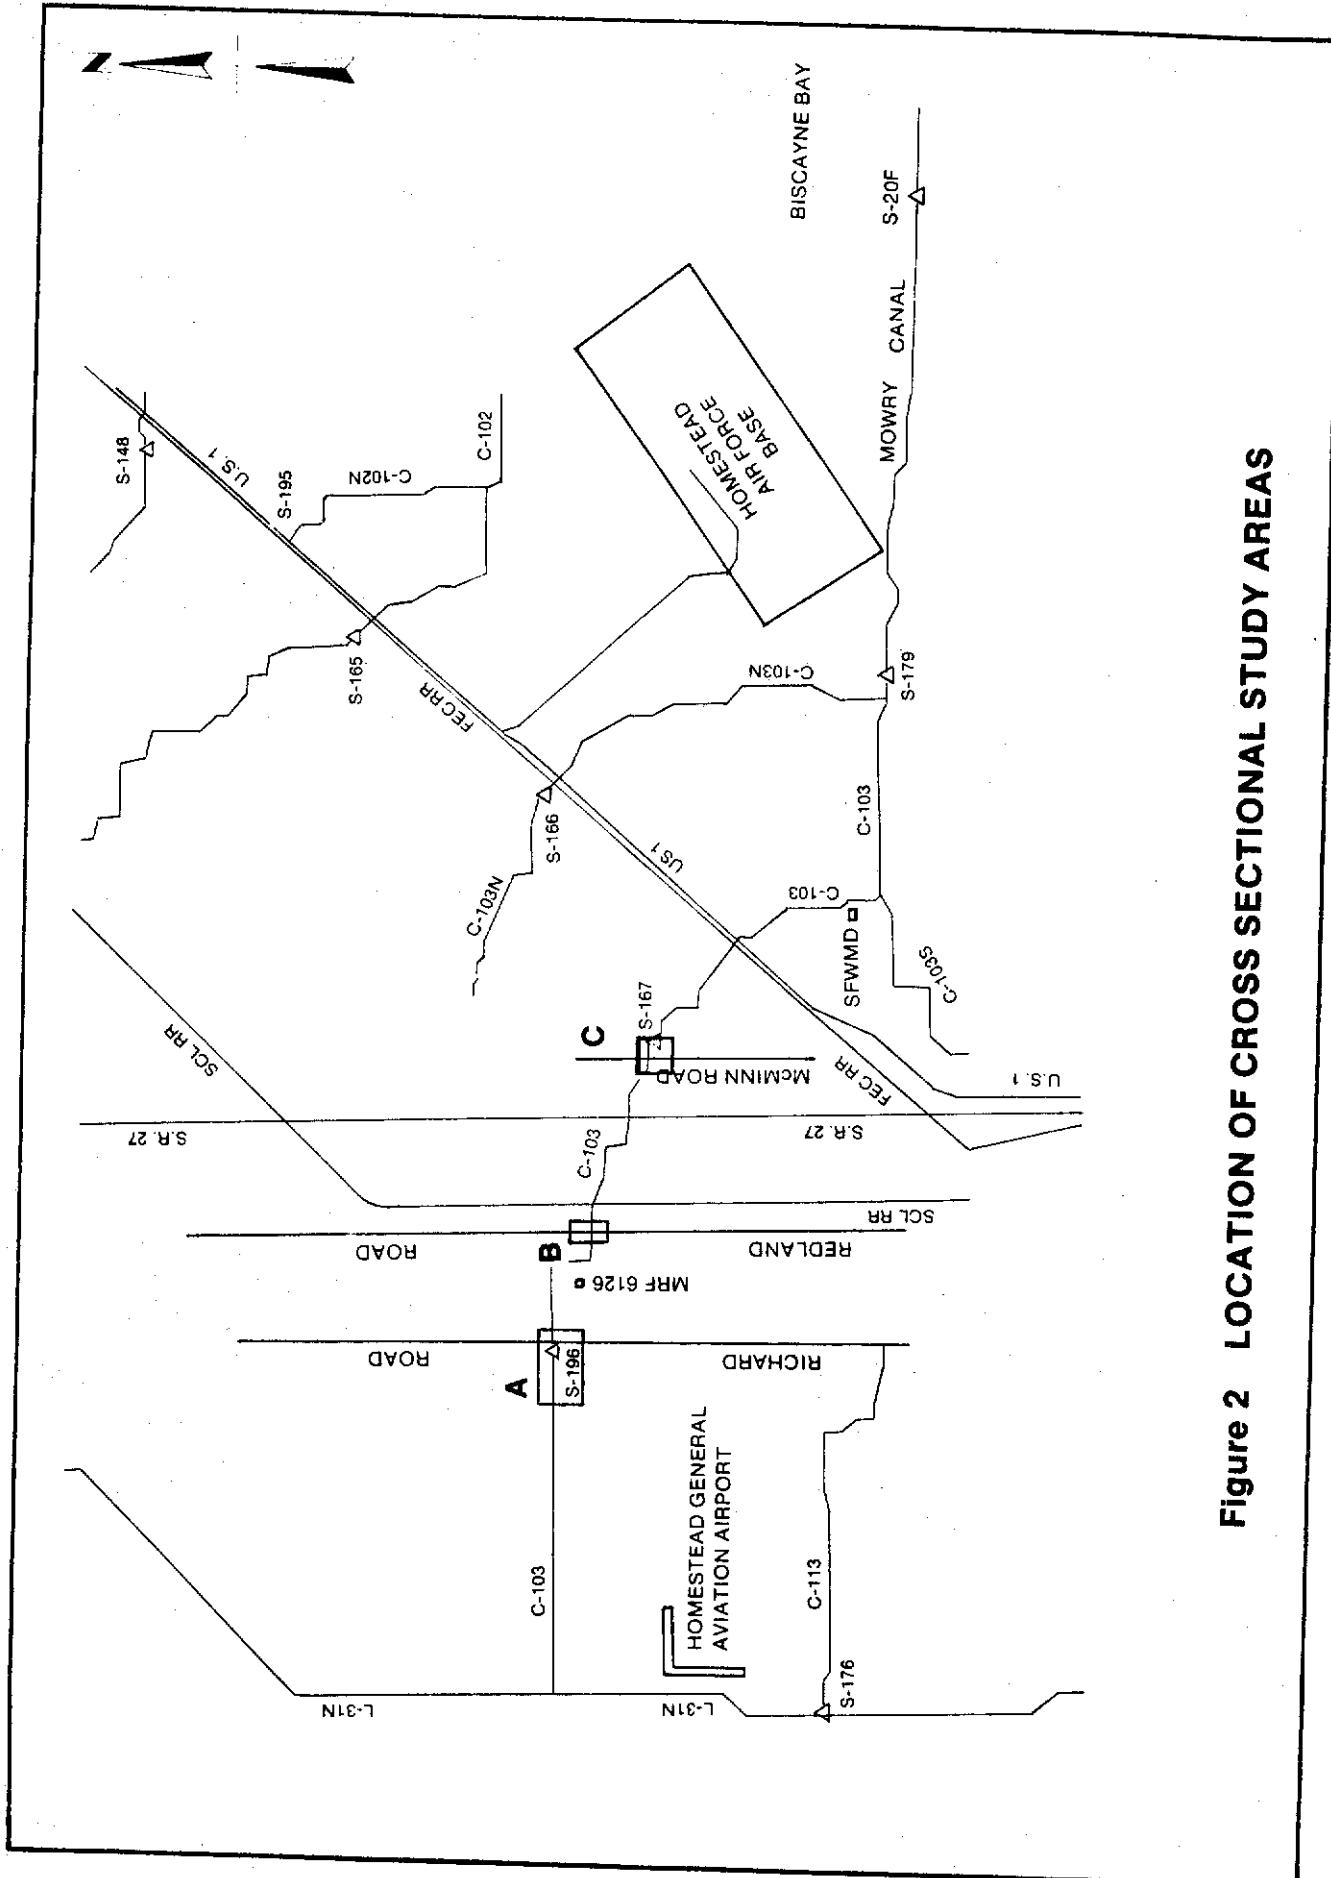

Cross Section A

An inset of the cross section (A) area is shown in Figure 3. The wells are normal to the canal and are approximately 850 feet west of structure S-196. Six wells (Nos. 1, 2, 3, 4, 5, and 6) were core drilled and are approximately 60 feet deep. A discussion of these cores is presented in a later section and a detailed description of each is presented in Appendix I. Wells 1A, 2A, 3A, 4A, 5A, 6A, 7A, 8A, 9A, and 10A were drilled using rotary air and are approximately 20 feet deep. The shallow wells have 20 feet of 6-inch schedule 40 PVC. The deep wells have 30 feet of 5-inch schedule 40 PVC and an inner casing of 3-inch schedule 40 PVC to a depth of 60 feet. The distance of each well from the top bank of the canal is shown on Figure 3. The shallow and deep well clusters were drilled to evaluate whether a low permeability layer, approximately 30 feet below land surface, confined the lower portion of the aquifer.

Cross Section B

An inset of cross section B area is shown in Figure 4. The wells are normal to the canal and are along the east side of Redland Road. There are two wells north of the canal (11A and 12A) and two wells south of the canal (13A and 14A). All wells were drilled to a depth of 20 feet using rotary air and completed with 20 feet of 6-inch schedule 40 PVC.

Figure 2 LOCATION OF CROSS SECTIONAL STUDY AREAS

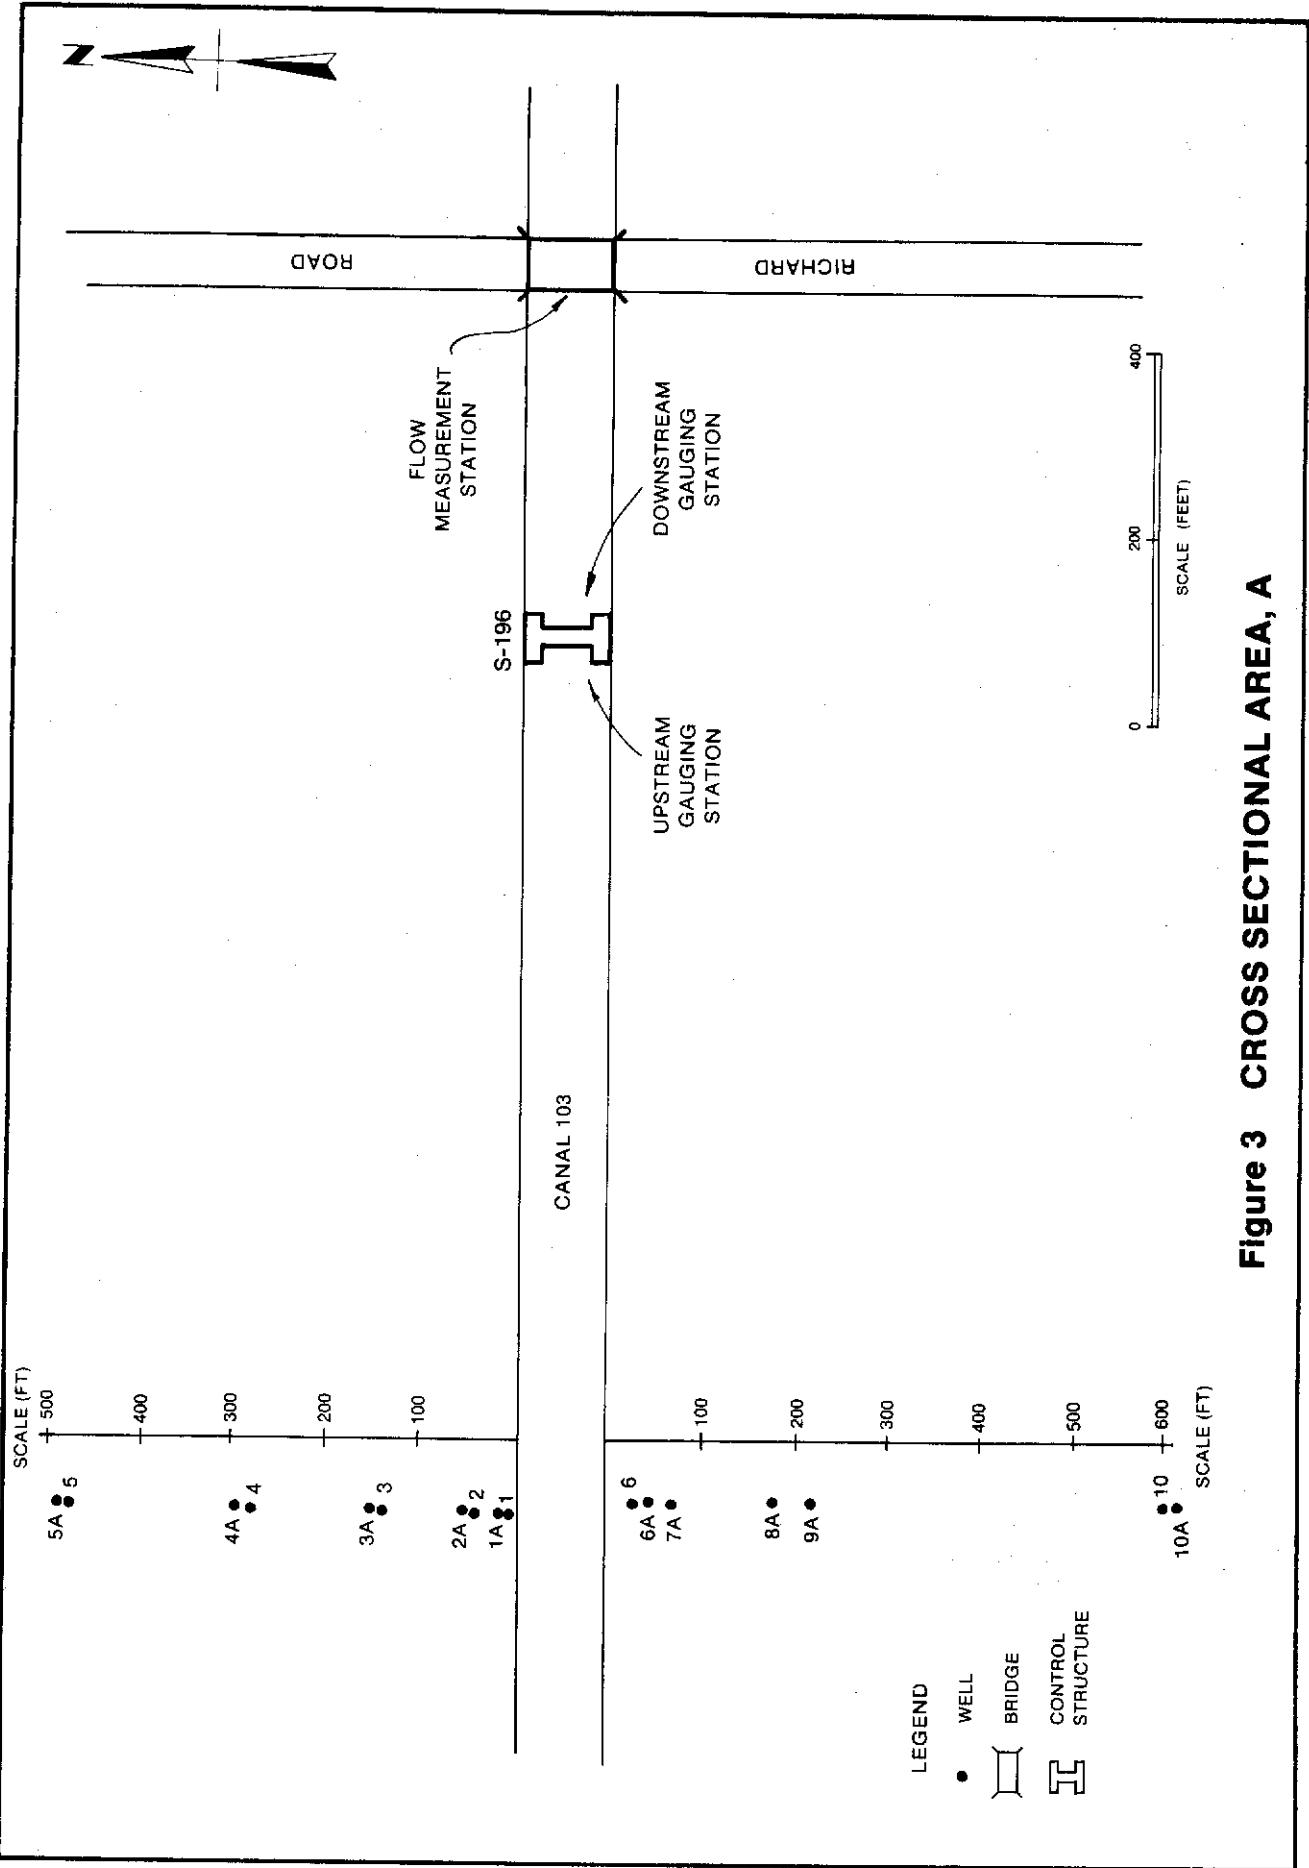

Figure 3 CROSS SECTIONAL AREA, A

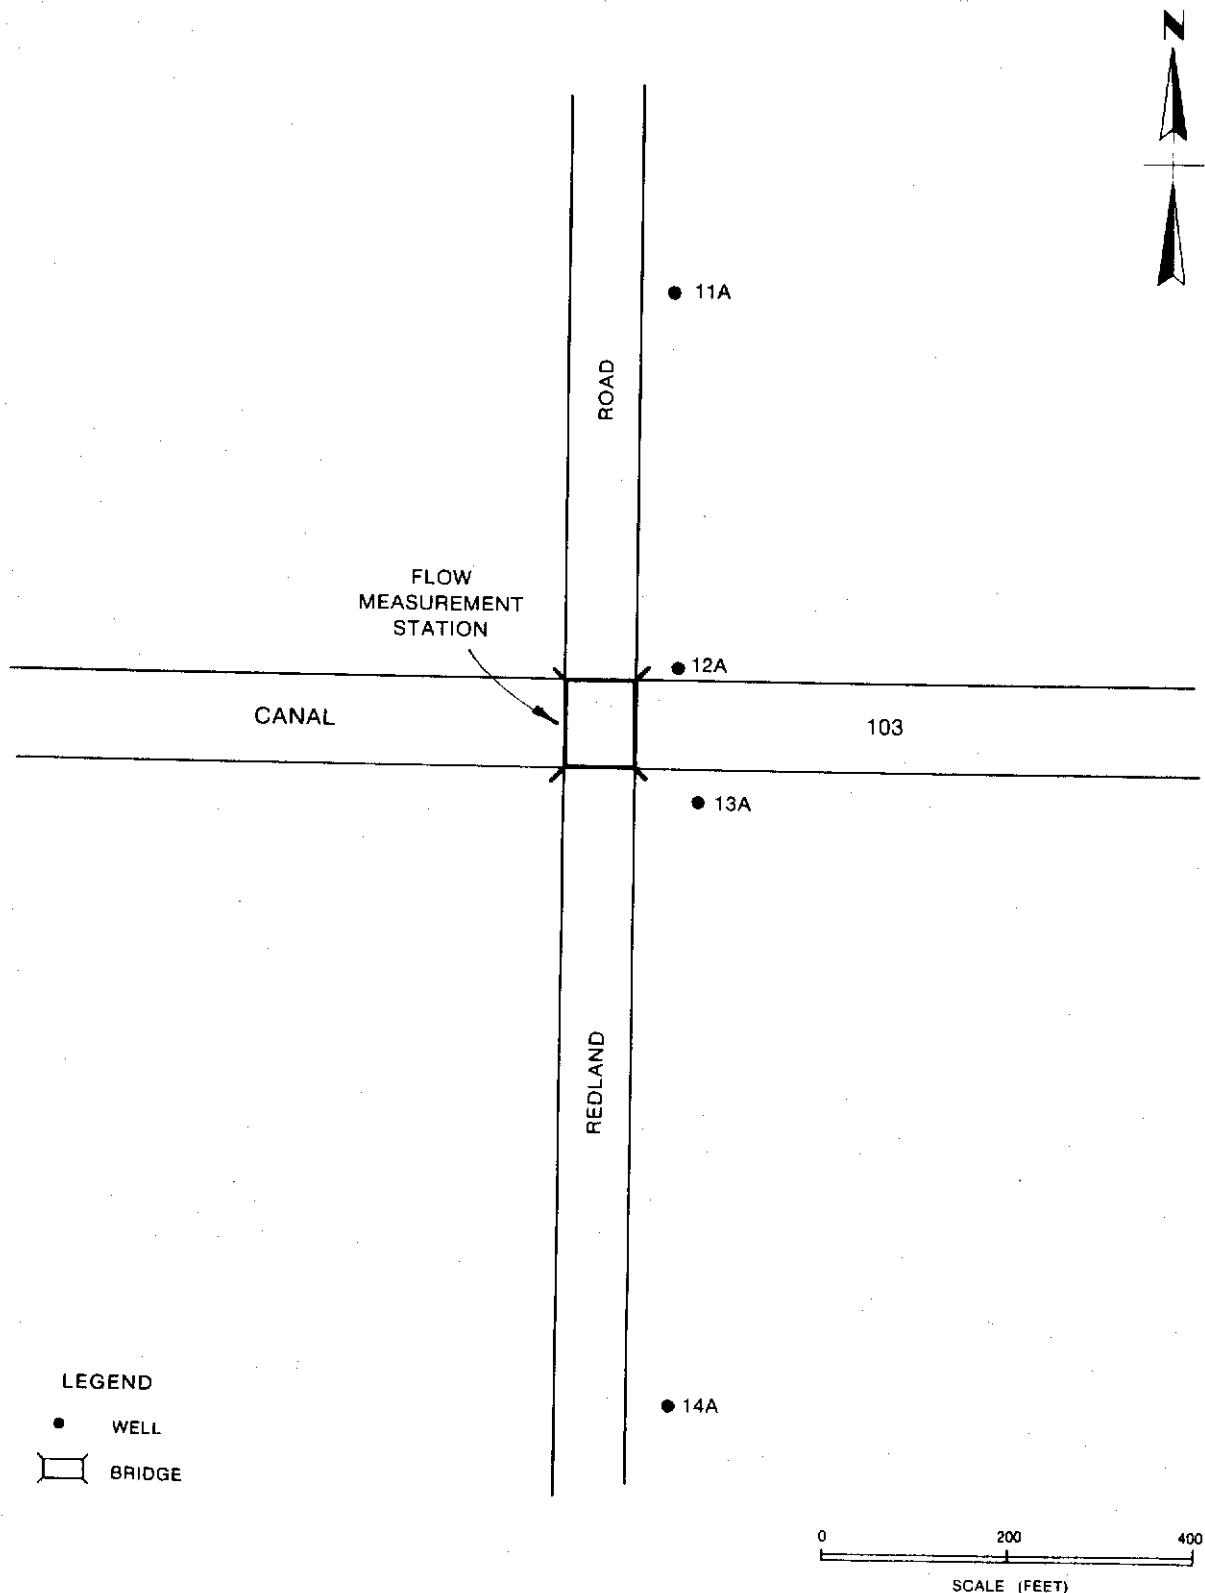

Figure 4 CROSS SECTIONAL AREA, B

Cross Section C

An inset of cross section C area is shown in Figure 5. The wells are normal to the canal and are approximately 700 feet west of S-167. There are two wells (15A and 16A) located in a nursery south of the canal. There are no wells to the north of the canal due to a lack of access. The two wells were drilled to a depth of 20 feet using rotary air and completed with 20 feet of 6-inch schedule 40 PVC.

Canal Stage Gauging Stations

There are two canal stage gauging stations along C-103. They are located at S-196 (Figure 3) and S-167 (Figure 5). S-196 is read from a staff gauge on weekdays. S-167 has a continuous stage recorder. The upstream and downstream stages at S-196 were recorded when all 23 wells were manually measured.

Flow Measurement Stations

Flow measurements were taken at three stations, one near each cross section, and the measurement locations are shown in the inset for each area (Figures 3, 4, and 5).

The flow measurement station for area A was along the west side of the Richmond Road bridge. This station is approximately 1,200 feet east of the wells and 350 feet east and downstream of S-196.

The flow measurement station for area B was along the west side of the Redland Road bridge. This station is approximately 200 feet upstream of the wells at cross section B.

The flow measurement station for area C was along the west side of the McMinn Road bridge. This station is approximately 700 feet west of the wells at cross section C and 1,400 feet upstream of S-167.

Water Quality Stations

Each of the 23 groundwater wells were sampled for water quality. In addition, a sample was taken from the canal near the cross section. Samples were collected at varying time intervals and analyzed for various parameters.

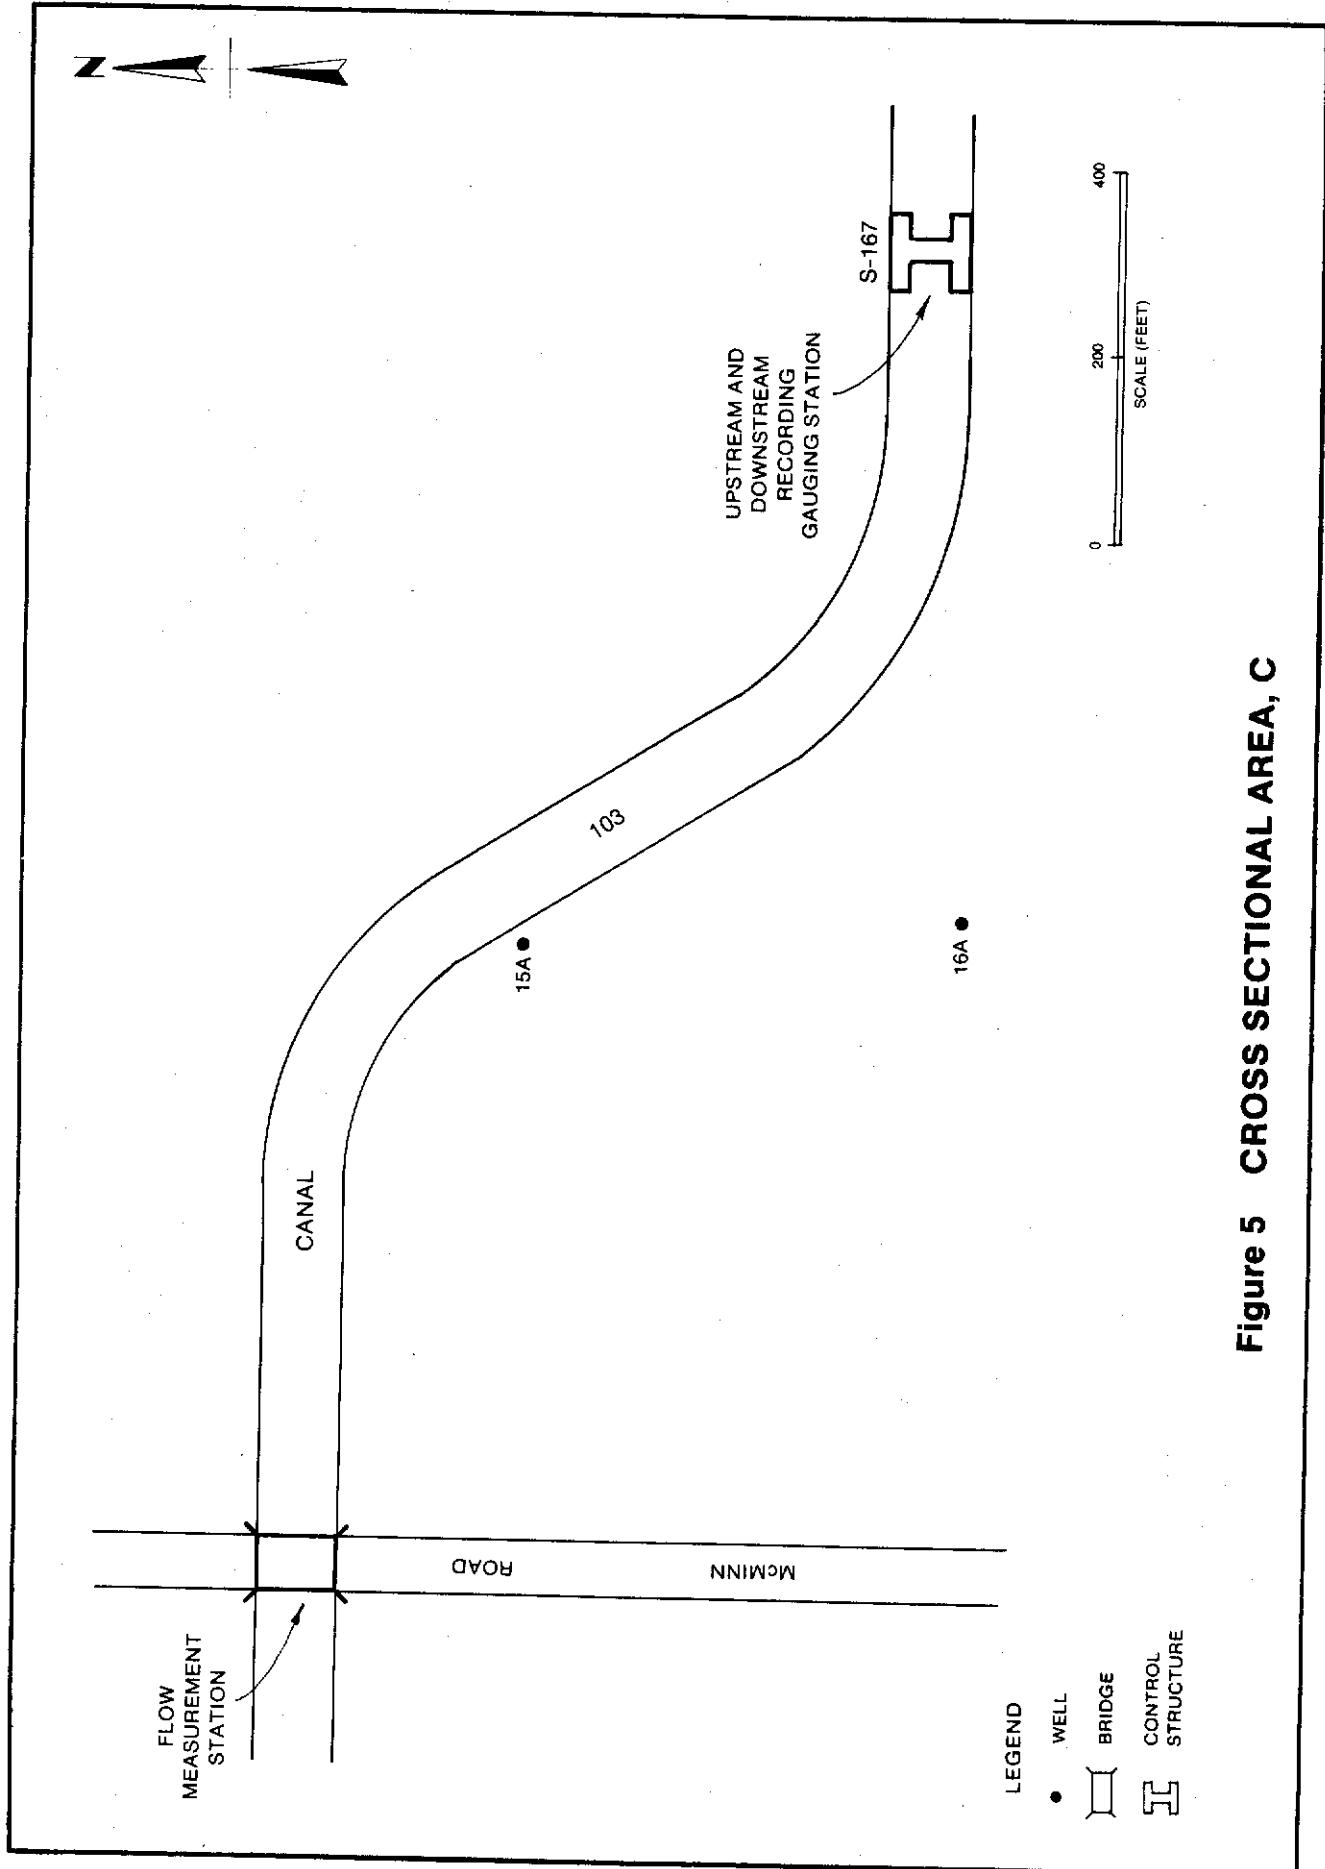

Figure 5 CROSS SECTIONAL AREA, C

GEOLOGY

A description of the general geologic and hydrogeologic characteristics in the C-103 and Homestead area is shown in Figure 6. A detailed description of each core is presented in Appendix I. The three formations present in the area, which are encountered to a depth of 60 feet, are the Fort Thompson formation, the Key Largo Limestone, and the Miami Oolite.

The Fort Thompson formation consists of alternating marine and fresh water limestones and marl beds, including between one to three fresh-water mudstones marked by the presence of the fresh water gastropod Helisoma sp. The upper portion of the Fort Thompson contains large numbers of the pelycypod Chione cancellata and is readily identifiable as the Coffee Mill Hammock member described by Schroeder et al., (1958). Groundwater percolation has caused solution cavities and channels to form in both the marine and fresh water beds. Sand and material from overlying beds have subsequently been deposited in some of these channels. These solution channels range in diameter from 0.5 to 2.5 cm. A bed of sandy limestone is present beneath the deepest fresh water mudstone bed. This sandy limestone bed is the lowest bed of the Fort Thompson formation and marks the contact between the Fort Thompson formation and the underlying Tamiami formation (Schroeder et al., 1958).

The Key Largo limestone was not present at Site A but is most likely to be present in the area as stringers interfingered with the Fort Thompson formation. The Key Largo limestone is a coralline limestone consisting of white to tan coral, fine grained crystalline limestone and generally grayish white sandy limestone reef deposits. The formation contains fine to medium grained cemented calcareous sand and other reef detritus and is generally well cemented. Vug content varies from abundant in certain zones to none in others. Fossil content includes the presence of Chione sp. and other mollusks.

Series	Formation	Geologic Characteristics	Aquifer Characteristics	Thickness In Homestead Area (feet)
P L E S T O C E N E	Miami Oolite	Limestone, white to yellowish-orange; oolitic. Contains up to 40% sand, stratified. Perforated with solution channels.	Fair to very highly permeable, especially in areas of solution channels and vugs	10-25
	Key Largo Limestone	Coraline limestone, white to tan coral, fine grained crystalline limestone and grayish white sandy limestone reef deposit. Fine to medium grained calcareous sand, vuggy.	Not present at Site A. Highly permeable where present.	0-15
	Fort Thompson Formation	Alternating marine and fresh water limestone, and sandstone.	Varying permeability. High where solution channels are open, but low where fresh water mudstones are deposited in the cavities, and near the lower contact with the Tamiami Formation	20-100

Figure 6 General Geologic and Hydrogeologic Characteristics of the Homestead Area.

The Miami Oolite found at Site A is a white to yellowish-orange massive oolitic limestone containing varying amounts of quartz sand (up to approximately 40 percent). Most of the sand tends to be concentrated in solution channels which range in size from about 1 to 4 cm and average approximately 1.5 cm in diameter. The formation is stratified and cross bedded.

HYDROGEOLOGY

A hydrogeologic cross section derived from the core samples collected at Site A is shown in Figure 7. The cross section shows the highly permeable Miami Oolite which ranges in thickness from 3 to 9 feet at the surface. Underlying the Miami Oolite is the Fort Thompson formation. The variation in permeability occurs where there are interfingerings of fresh water mudstones. The lenses are predominant at depths of approximately 35-40, 45-48, and 50-55 feet below land surface, with thickness averaging 2-5 feet.

At Site A the Miami Oolite is highly permeable. The Fort Thompson formation, though similar in structure, appears less pervious than the Miami Oolite and Key Largo Limestone (where present). The solution channels and vugs present in all three formations are responsible for virtually all of the water flow through the individual formations. Secondary solution along formation contacts is also a contributor to water flow through the aquifer. The lower permeability of the Fort Thompson formation is due to the fact that it has smaller, less numerous channels and vugs than the other formations; in addition, some of the channels in the Fort Thompson formation are partially filled in by sediment. Both of these factors tend to lower the mass permeability of the rock.

The results of the laboratory permeability test are shown in Tables 1 through 6. The data indicate that the Miami Oolite has a higher permeability

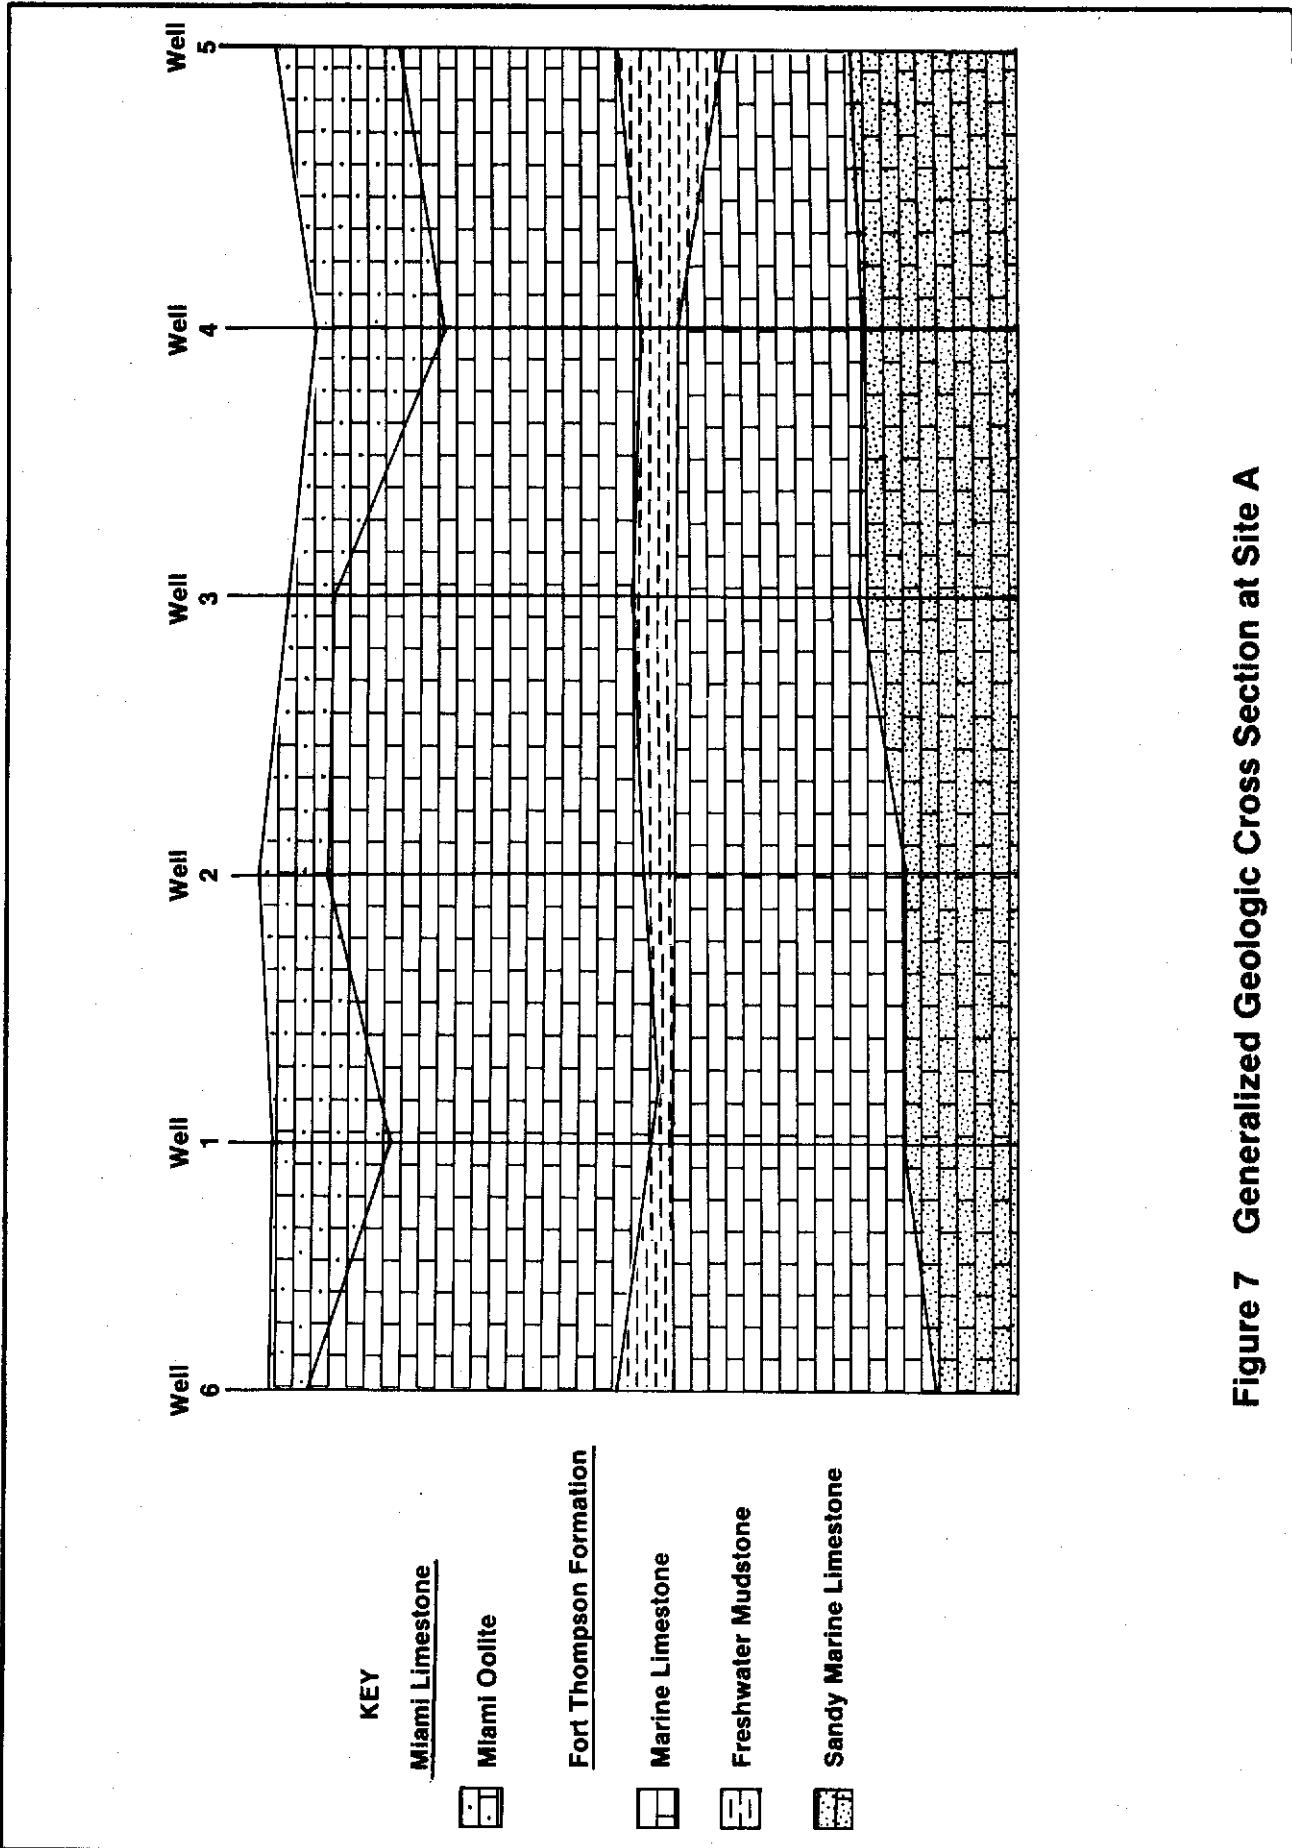

Figure 7 Generalized Geologic Cross Section at Site A

than the Fort Thompson formation. Tests show that the Miami Oolite at Site A has a range of permeability from a high of 0.395 cm/sec to a low of 0.113 cm/sec with a mean permeability of 0.187 centimeters per second (cm/sec). The Fort Thompson formation has a range of permeability from a high of 0.394 cm/sec to a low of 0.00024 cm/sec with a mean permeability of 0.036 cm/sec.

The relationship of rock type to the permeability is shown for each of the six core samples in Figures 8, 9, 10, 11, 12, and 13. The highest permeability is in the upper 20 feet where the Miami Oolite is present. The limestone has varying degrees of permeability depending on the pore space interconnection and particle size. The coralline limestone has a moderate permeability.

WATER LEVELS

Canal-Aquifer Relationship

Figure 14 depicts the simultaneous groundwater levels and canal stages at each of the three cross sectional areas. Site A has the highest levels with the canal stage being 3.48 feet above NGVD, while the aquifer adjacent to the canal is approximately .25 foot lower than that ranging from 3.21 to 3.27 feet above NGVD. It is apparent that Figure 14 has a large vertical exaggeration (X800) and actually the differences in water levels is very slight. The groundwater stages show that the aquifer has a very flat surface within a 600 foot radius of the canal (fluctuating only .06 foot), and allows the canal to recharge the aquifer through this small gradient. It was noted earlier that at this site, shallow and deep wells were drilled to determine if a head difference existed at the 20 foot and 60 foot depth. The actual measured differences between these adjacent shallow and deep wells rarely exceeded .01 to .02 foot. Therefore, it was concluded that there was no head difference and the water level data from the shallow well is generally used.

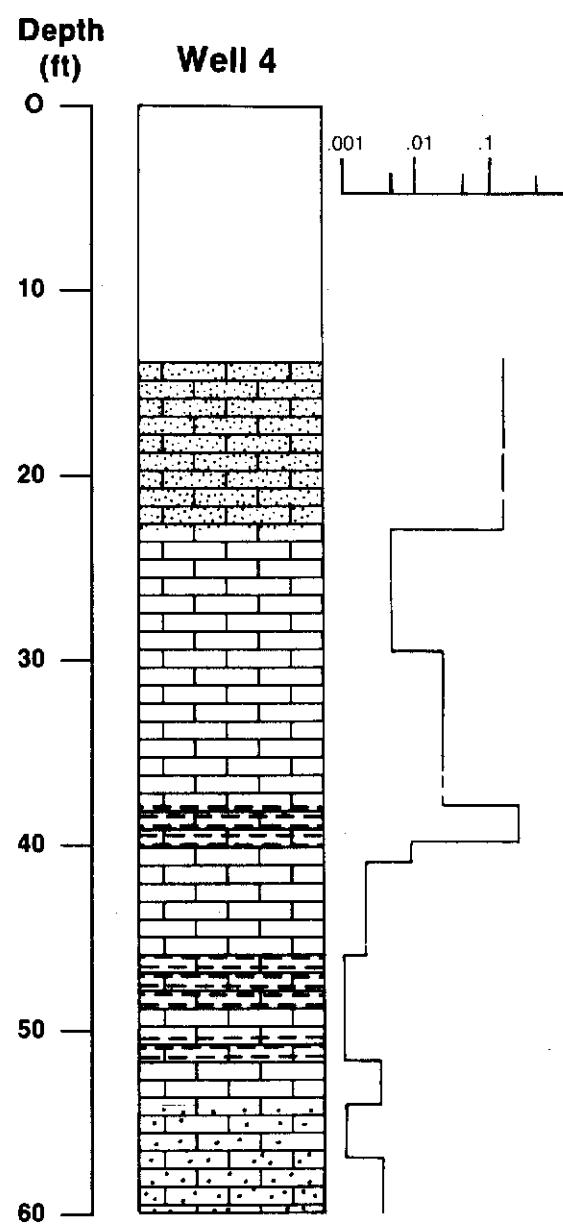

Figure 11 Geology and Permeability of Well 4

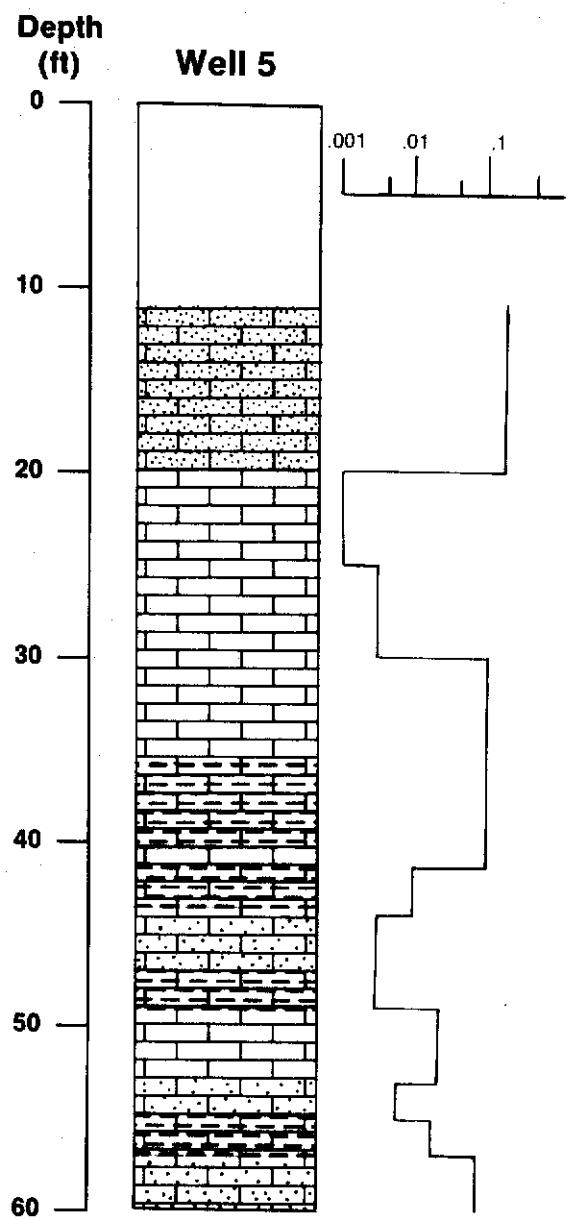

Figure 12 Geology and Permeability of Well 5

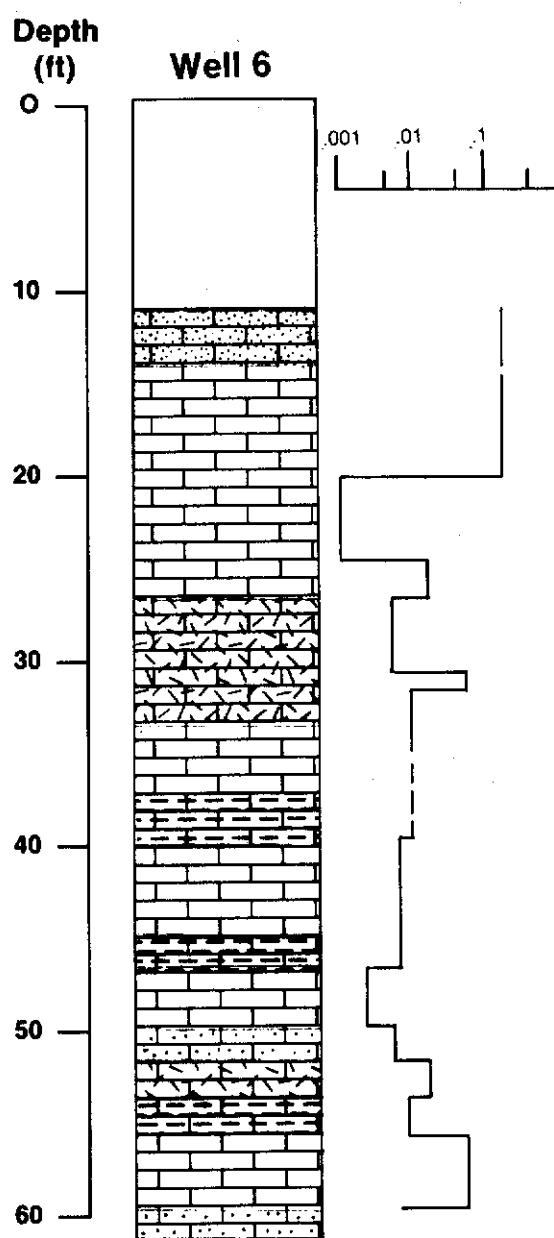

Figure 13 Geology and Permeability of Well 6

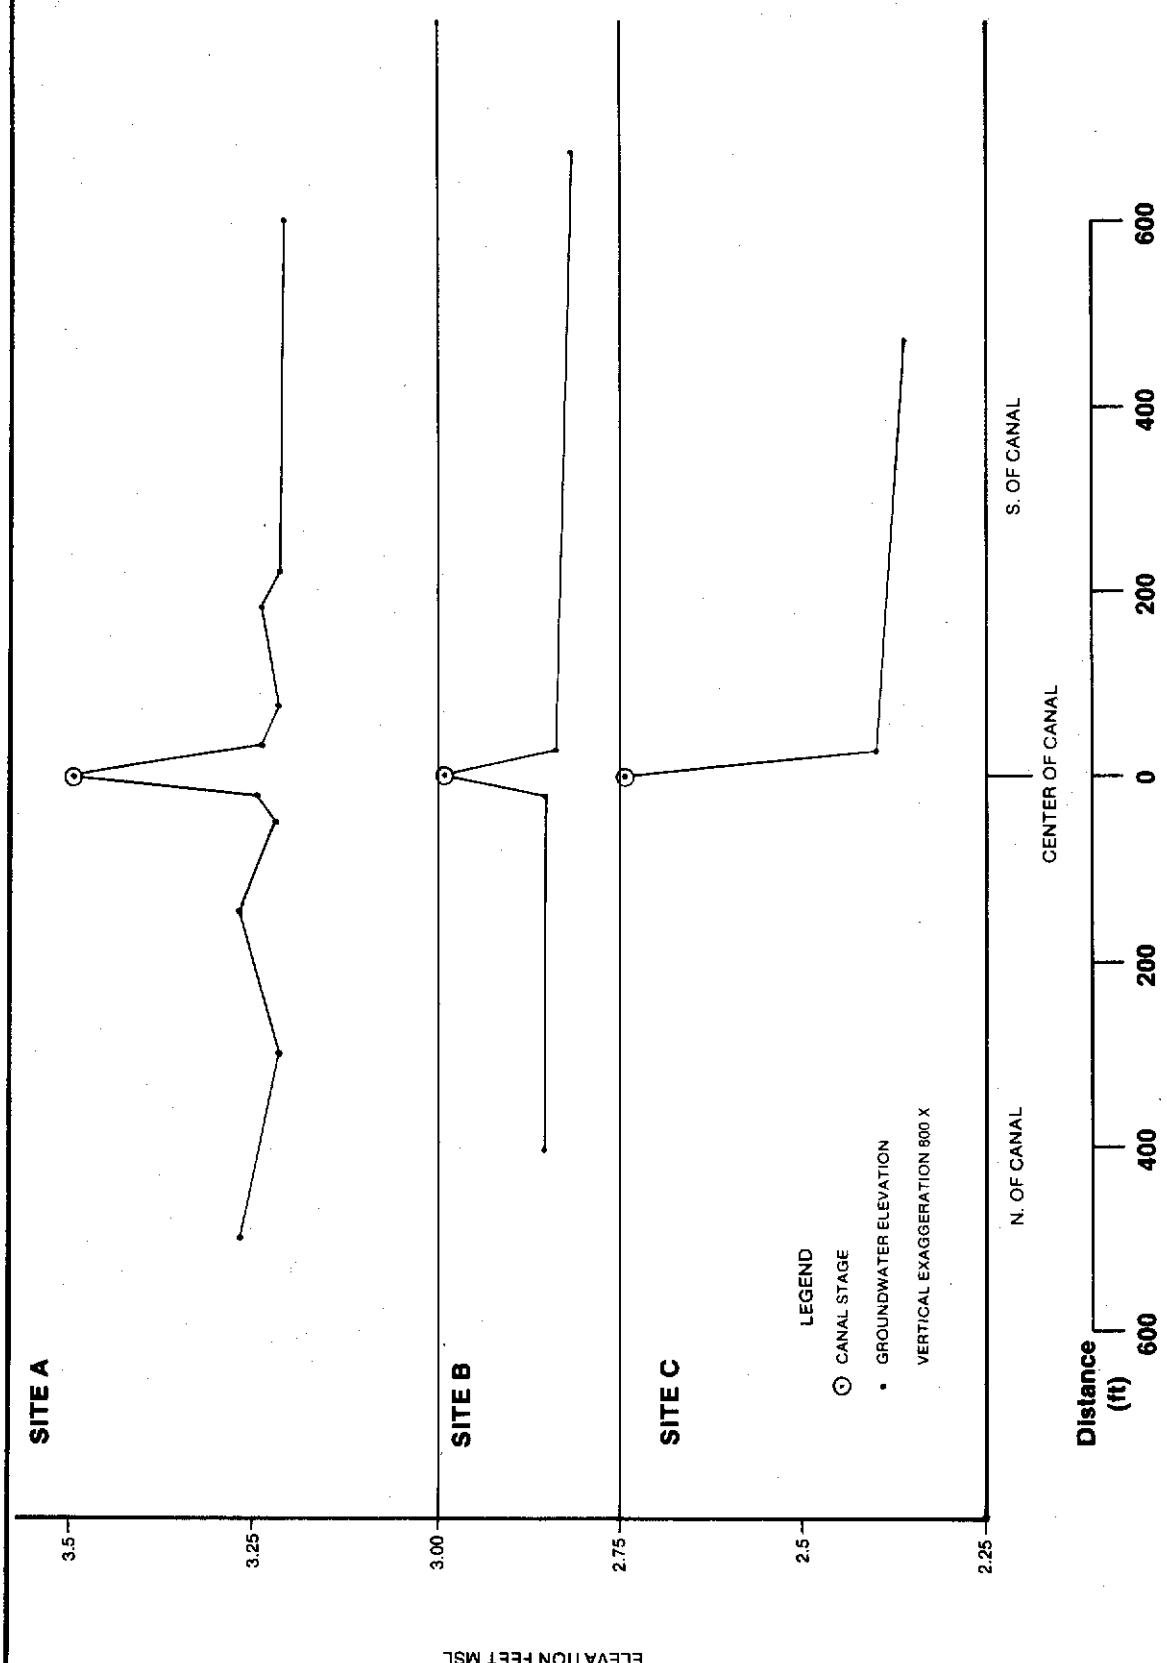

Figure 14

COMPARISION OF SIMULTANEOUS VALUES BETWEEN CANAL STAGE AND GROUNDWATER LEVELS

The same situation occurs at Site B where the canal stage was 2.97 feet above NGVD while the adjacent groundwater levels ranged from 2.82 to 2.85 feet above NGVD. This similar case reflects a .12 to .15 foot head difference from the canal to the adjacent aquifer and only a .03 foot difference within the aquifer itself.

Site C, while having only two wells, still shows the same relationship. The canal is approximately .35 foot higher than the very flat aquifer surface.

These very low gradients between the aquifer and the canal are due to: 1) the high transmissivity of the aquifer, and 2) the high degree of hydraulic connection due to the very porous and permeable nature of the rock.

The advantages and disadvantages of the inter-connection was discussed by Klein and Hull (1978).

"The benefits area: (1) Flood prevention by the rapid removal of excess water to the ocean through operation of control structures in canals; and (2) the movement of ground water from the interior to the coastal areas where it can infiltrate the aquifer and maintain high water levels to retard saltwater intrusion. Problems related to good aquifer-canal interconnection are: (1) The movement of saltwater into the aquifer along the coast and tidal canals during times of low water; and (2) the threat of pollutants entering the aquifer from the land surface or from canals, and moving long distances."

The relationship between the water level readings from the wells and the canal stage is linear and has a very high correlation. Figure 15 shows linear regression analysis plots of the water levels in wells 6A and 7A as compared to the stage at S-196, and the water levels in wells 15A and 16A as compared to the stage at S-167. Each of the data points indicate the canal stage to be higher than the aquifer elevation. The linear regression for well 7A versus C-103 stage at S-196 has a near perfect slope of one. The y intercept at .21 foot confirms the observations from Figure 14 indicating the canal stage to be approximately .2 foot above the adjacent aquifer elevation. These linear relationships can be useful in the absence of data to predict heads when given either canal stage or aquifer elevation data.

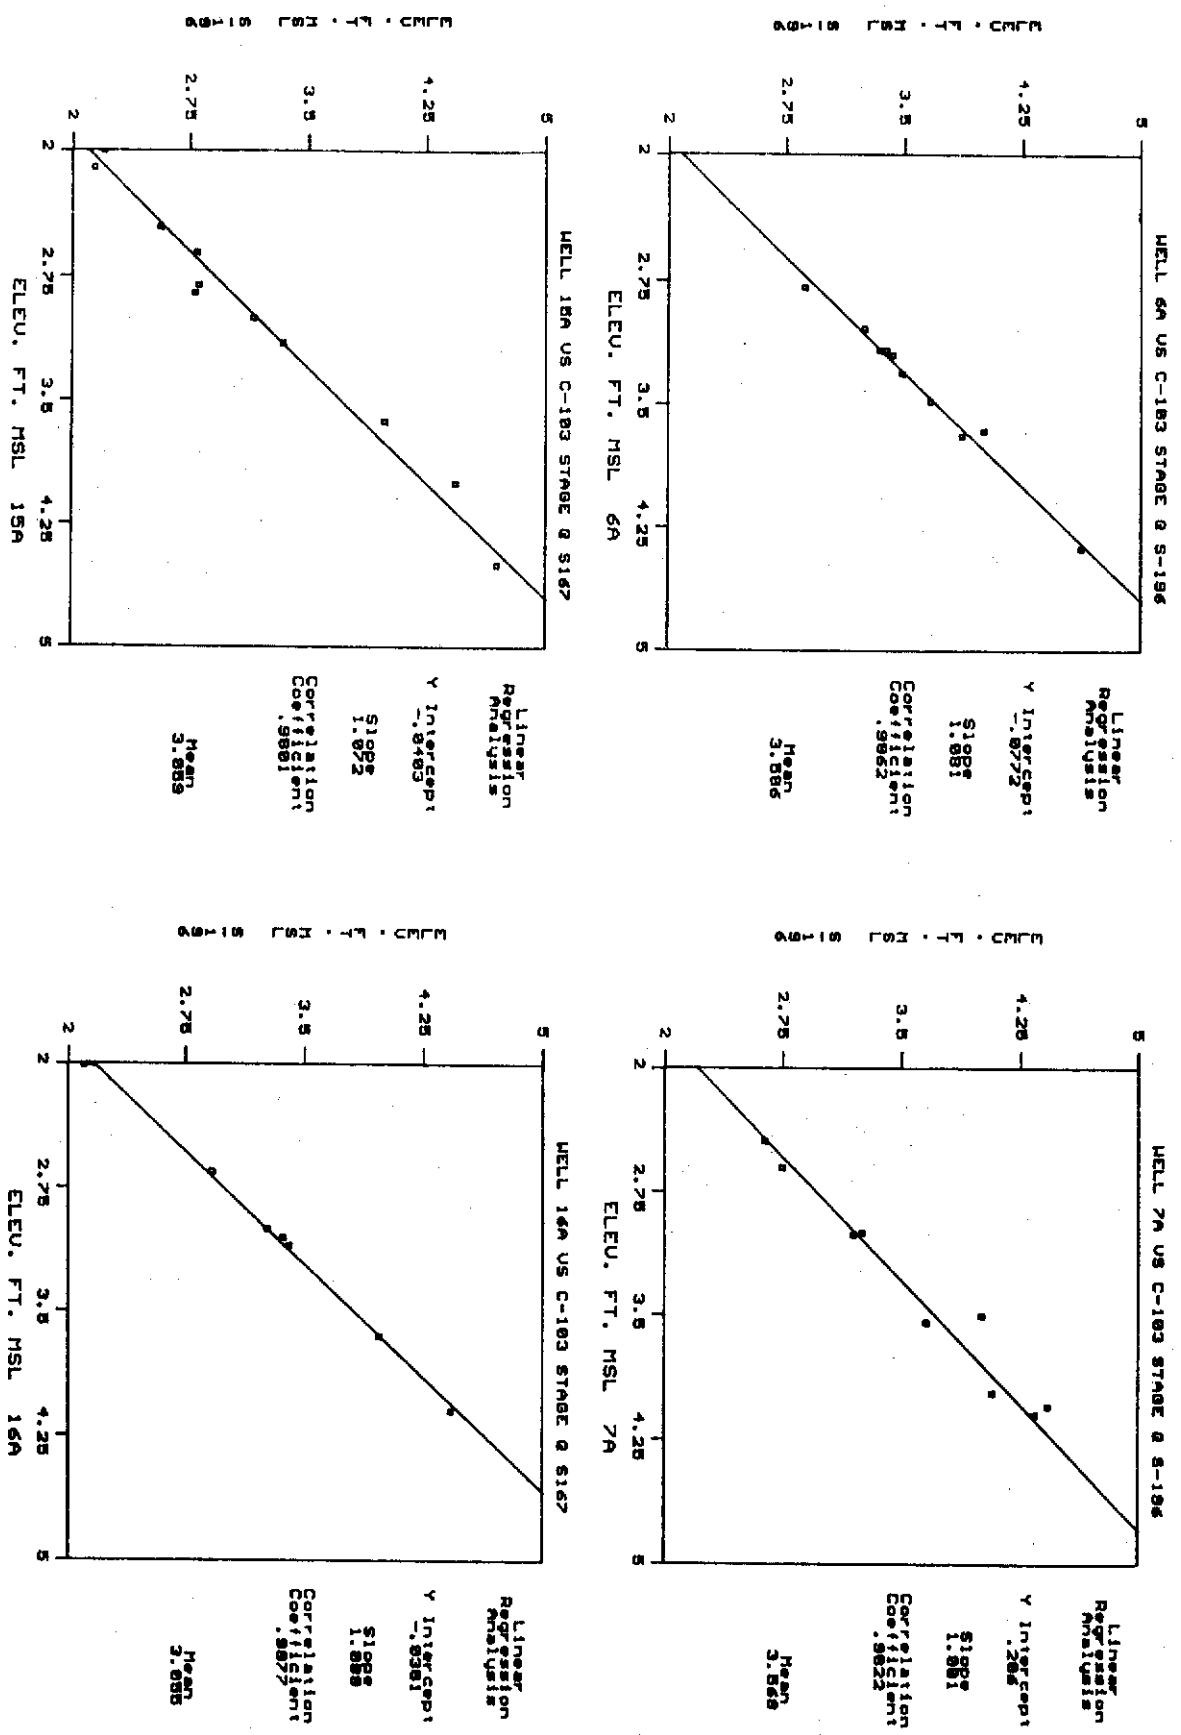

Figure 15 LINEAR RELATIONSHIPS BETWEEN CANAL STAGE AND GROUNDWATER LEVELS

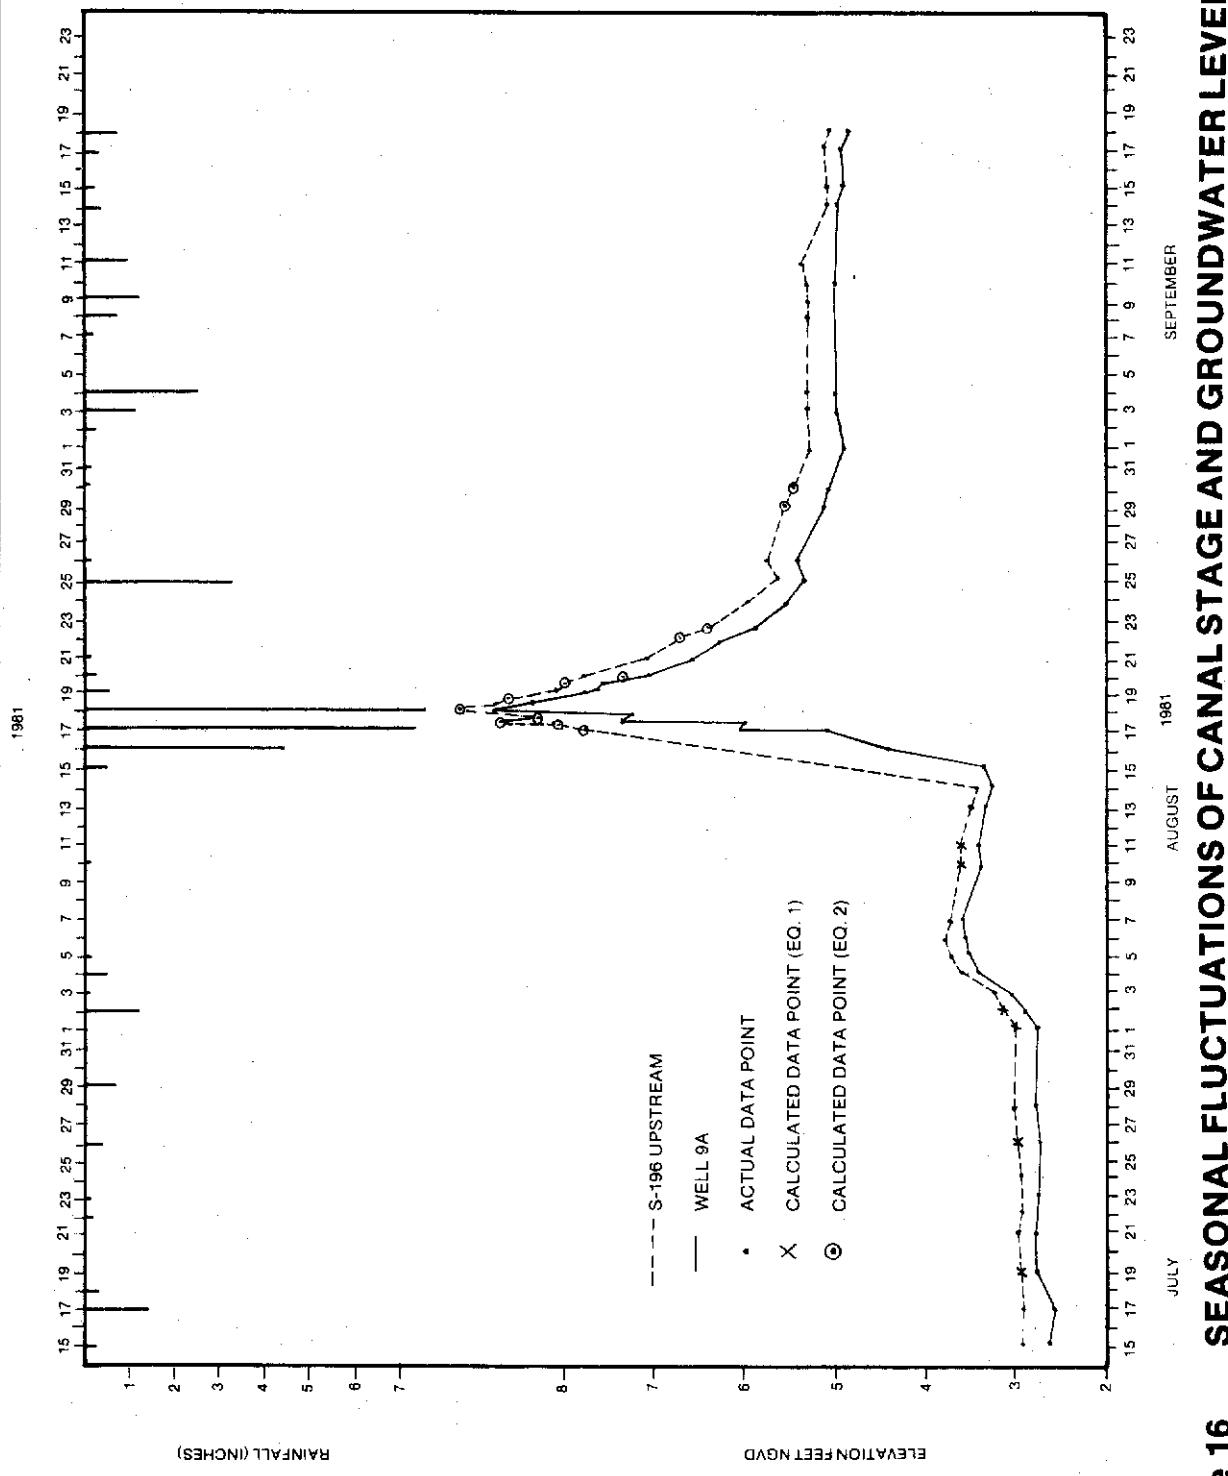

Seasonal Fluctuations

Between January and June 1981, 14.15 inches of precipitation were recorded at rainfall gauging station MRF6126 (Figure 1). From July to December of the same year, 60.57 inches of rain fell in the C-103 vicinity. Figure 16 illustrates the daily rainfall and its effect on the C-103 stage and groundwater levels. The data used to plot the groundwater elevation is from well 9A, and the stage data from S-196 upstream, both located at Site A.

As previously discussed, the strong linear relationship between the well data and the stage data allows for the prediction of either canal or groundwater stages in the absence of water level data. At site A the well data is taken from a continuous strip chart recorder while the canal stage is read from a staff gauge. For this reason, there was more water level data while some stage data was missing (especially on weekends). Therefore, the linear equation

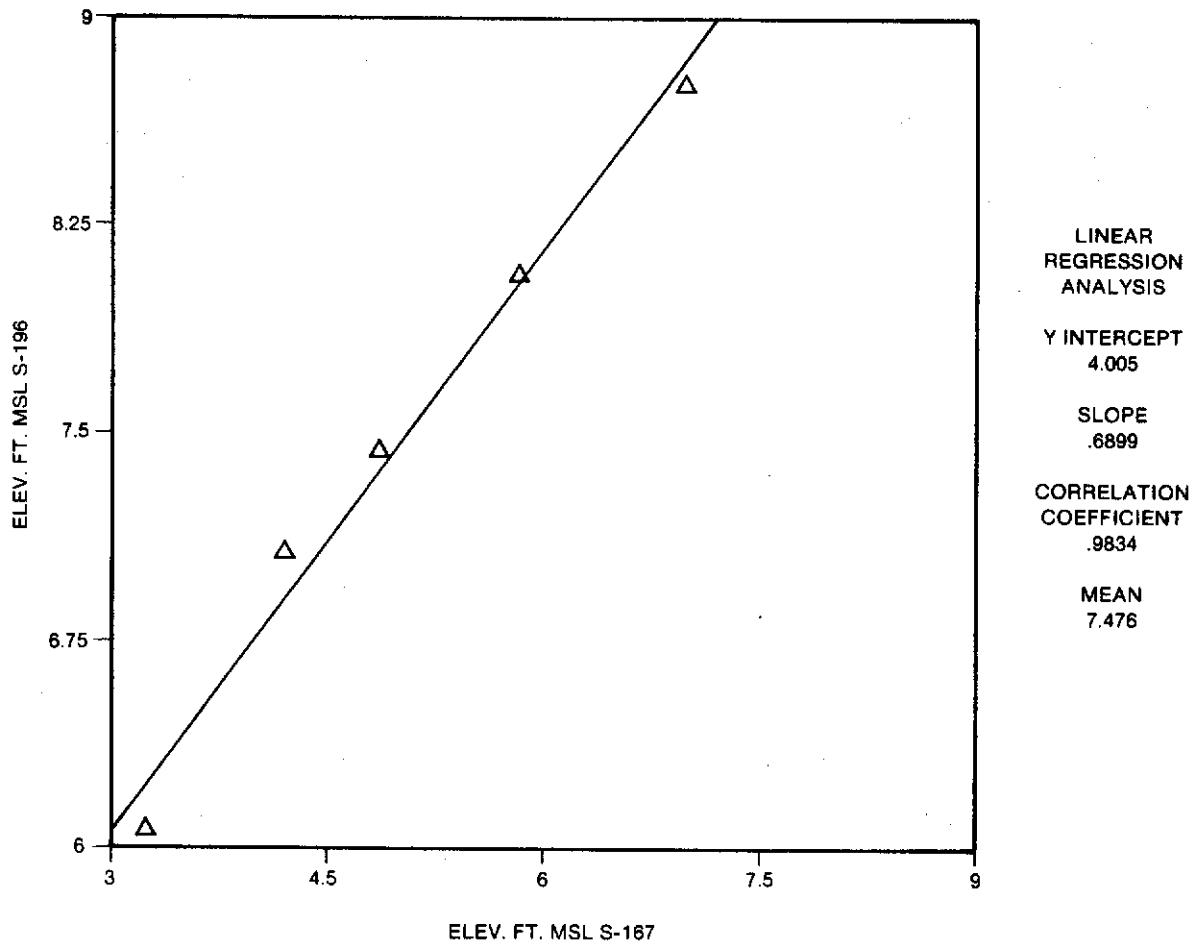

$$y = 1.001 X + .206 \quad (1)$$

was used for missing early time stage data in Figure 16. These values are depicted by an X. In addition, the storm event in mid-August required more frequent readings than the data available from the S-196 staff gauge. It was readily apparent from empirical observation that equation (1) did not hold true for high rainfall (or high gradient) periods. In addition, S-167 was equipped with a continuous recorder which recorded the storm event precisely. Therefore, an additional linear equation relating values from S-167 to S-196 during high water periods (Figure 17) was used for comparison with the water levels in well 9A. These values are depicted on Figure 16 by an O. Note that there are actual S-196 staff readings taken during the event that helped calibrate the curve.

SEASONAL FLUCTUATIONS OF CANAL STAGE AND GROUNDWATER LEVELS COMPARED WITH RAINFALL

Figure 16

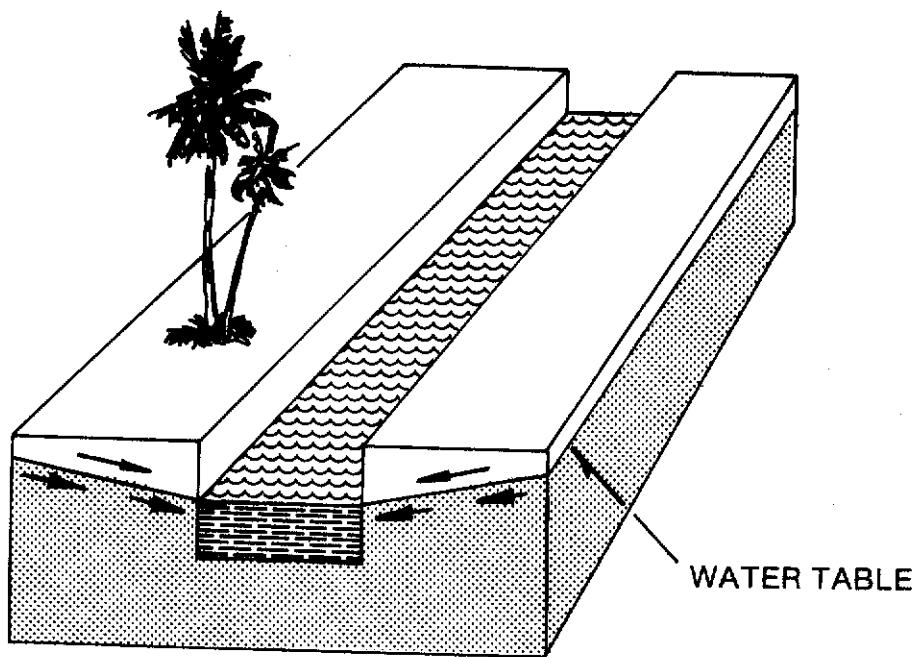

**Figure 17 LINEAR RELATIONSHIP BETWEEN S-196 AND S-167
DURING HIGH WATER LEVELS**

The linear equation used from Figure 17 is

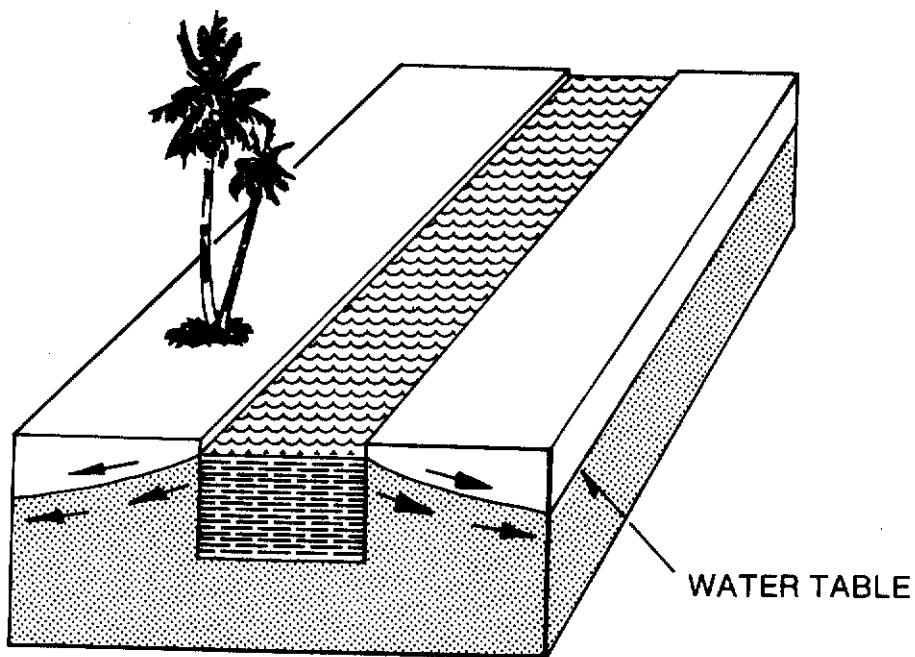

$$y = .690 X + 4.10 \quad (2)$$

The water levels in mid July represent the typical dry season or low water elevation of 2.5 to 3.0 feet above NGVD. A storm event in early April increased levels to approximately 3.5 feet above NGVD. Water levels began to recede until August 14, 1981 when a major storm event began. Between August 14, 1981 and August 19, 1981, 21 inches of precipitation was recorded at rainfall gauging station MRF6126. This caused a sharp rise of both the aquifer and canal levels. The canal peaked at 9.15 feet above NGVD and the aquifer rose to 8.80. Water levels then again receded until August 25, 1981, when 6.5 inches of rain increased levels slightly. By September 1981, the water levels were approximately 5 feet above NGVD, and slowly dropping.

During this entire span, illustrated in Figure 16, the canal stage remained above the aquifer and by a relatively constant amount. In fact, the author has been unable to find a single instance when the groundwater table was above the canal stage, even during dry periods when this scenario might be expected. The situation is shown graphically in Figure 18 taken from Klein and others (1975). During the entire period of record for this study the situation, as depicted in the lower portion of the figure, has occurred. Even during low canal stages, as shown in the upper portion of the figure, the inflow of water to the canal does not occur. This is due to the water management practices of maintaining high canal stages. Headwater design criteria for S-167 is 5.6 feet above NGVD, and for S-196 the headwater is 6.5 and the tailwater 5.5 feet above NGVD. Therefore, the gates are usually closed to attain these regulation stages.

When the water level in an aquifer is higher than that in a canal that penetrates it, water moves toward the canal.

When the water level in a canal is higher than that in the aquifer it penetrates, water moves into the aquifer.

**Figure 18 — Hydraulic connection between a canal and an aquifer
(Klein and others, 1975)**

FLOW MEASUREMENTS

Discharge measurements were made at four locations along C-103; two at Site A and one each at Sites B and C. Measurements were taken using a handheld Price type AA four-vane vertical axis meter. Summaries for the discharge measurements made at each location are shown in Tables 7 through 10.

Table 7 shows that an attempt was made to measure flow upstream of S-196. This was a difficult location to transect and the abundance of weed did not allow the flowmeter to turn. Zero discharge was measured at this station and it was subsequently dropped.

Table 8 shows the discharge measurement approximately 350 feet downstream of S-196 at the Richard Road bridge. Average discharge for the four measurements taken was 7.75 cubic feet per second (cfs). One reading was taken on 2/18/81; however, since it rained approximately 5 inches that evening a new measurement was taken on 2/19/81. The velocity increased from .25 feet per second (fps) to .38 fps, as did the discharge which increased from 7.35 cfs to 11.5 cfs.

Table 9 is the discharge measurement for Site B taken at the Redland Road bridge and C-103. The velocity and the discharge were relatively constant during the three measurements. The velocity averaged .21 fps and the discharge averaged 35.5 cfs.

Table 10 shows the three measurements taken for Site C at the McMinn Road bridge and C-103. The mean velocity for the three readings averaged .13 fps and the discharge averaged 18.33 cfs.

WATER QUALITY

A complete summary of all water quality samples collected between 7/15/79 and 3/1/83 is found in Appendix II. As many as four samples per well were collected and up to 28 parameters analyzed. Appendix II is organized by

station and gives the number of values, average standard deviation, minimum value, and maximum value for each parameter.

The concentration of major ions can be evaluated using the Piper trilinear diagram (Figure 19). The sample plot in the diamond is indicative of sodium bicarbonate type waters. These are indicative of freshly recharged water in a carbonate aquifer. All of the wells are fairly closely spaced in Figure 19 (which includes samples from all stations) indicating similar sources and geochemical conditions in the aquifer.

To evaluate changes in water quality with time, additional post pumping data must be examined. It has been noted that recently there has been an apparent increase in iron; however, an evaluation of this situation is beyond the scope of this report. Since it has been mentioned that the canal stage is higher than the aquifer, allowing contaminants to enter the aquifer from the canal, additional analyses for pesticides, herbicides, and other organics should be made.

HOMESTEAD WATER QUALITY DATA FOR ALL STATIONS

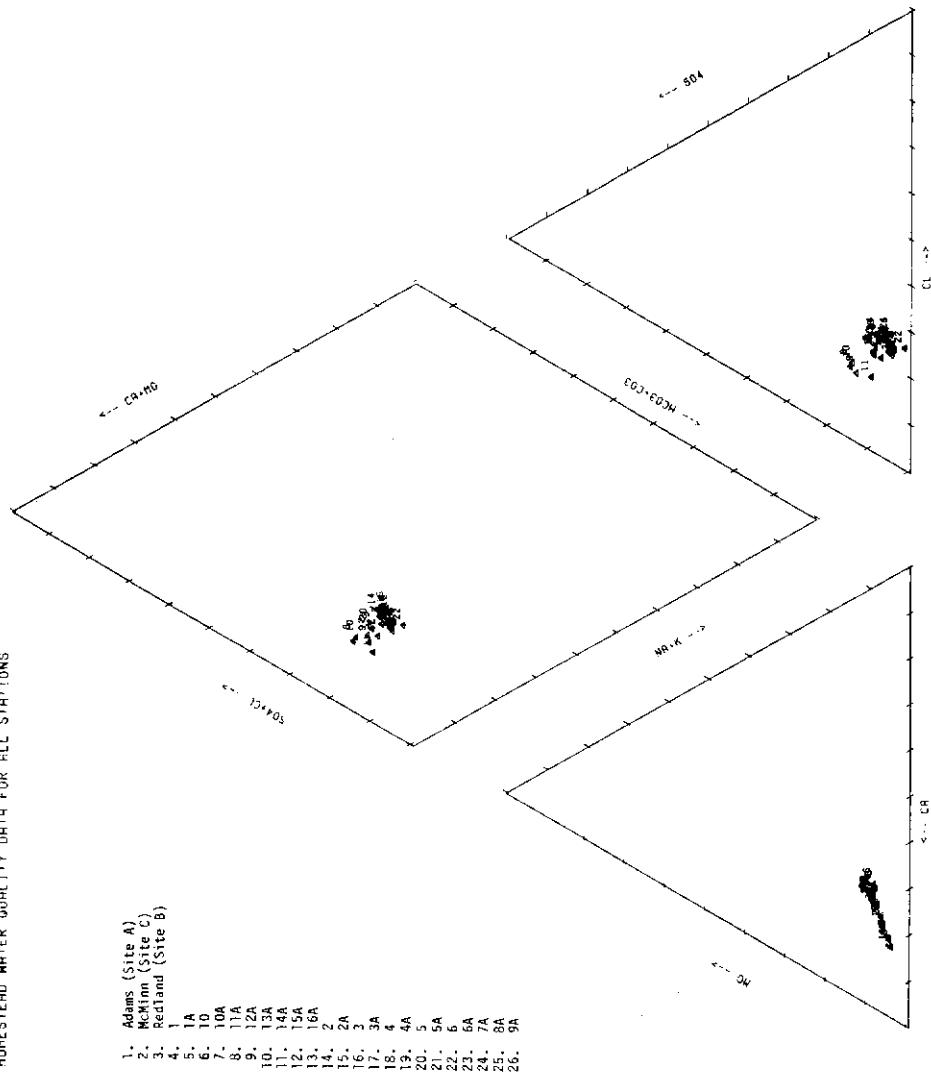

Figure 19 Piper Trilinear Diagram for All C-103 Sampling Stations

CONCLUSIONS

1. The surface of the aquifer in the C-103 area is extremely flat, deviating approximately .06 foot within 600 feet of the canal.
2. C-103 maintained a higher elevation (approximately .25 feet) than the adjacent groundwater levels throughout the period of study.
3. The aquifer and the canal respond rapidly to rainfall events and show similar hydrographs throughout a rainstorm event.
4. The canal rarely reaches regulation stage, and the gates are generally kept closed.
5. The permeability of the upper 25 feet of the aquifer is extremely high as water flows through large interconnected pores.
6. There is a lower permeability layer present at a depth of 30 feet; however, it is not confining enough to cause a difference in head between the shallow (20 feet) and deep (60 feet) wells.
7. The high degree of interconnection between the aquifer and the canal is beneficial in that it is effective for flood protection. The movement of groundwater east from the water conservation areas helps maintain high water levels, thereby retarding saltwater intrusion. However, from a water quality viewpoint, it is detrimental due to the threat of pollutants entering the canals and increasing the extent of contamination.
8. A linear equation of,

$$y = 1.001 X + .206$$

can be used to predict canal stage from nearby aquifer elevations during low stage periods.

9. Flows were low and recorded mainly seepage around the structures. Velocities are at the lower limit of detection for the meter used.
10. Water quality data is fairly uniform and representative of calcium bicarbonate type water.

RECOMMENDATIONS

1. Since the changes in water level readings are less than .25 foot, very accurate data is needed. The constant gradient from the canal to the aquifer, even during low water periods, is questionable. Therefore, each well and each staff gauge or stage recorder station should be resurveyed to insure accuracy.
2. Continue water quality monitoring to evaluate changes in water quality, especially iron, and analyze for organic contaminants when possible.
